A TWIN-CHANNEL ELECTRONIC SWITCH

B.E. Bourne

### ABSTRACT

A twin-channel electronic switch is described for use with a single-beam oscilloscope. Two transient or steady-state audio frequencies having components up to 20 kilocycles per second can be observed at the same time by switching the sweep vertically at a rate which is variable up to  $10^5$  times per second and sampling the audio frequencies in turn. In appearance the result is two horizontal sweeps with separate signal inputs to each.

## A TWIN-CHANNEL ELECTRONIC SWITCH

### Introduction

The conventional electronic switch in general use, with a switching rate of from 30 to 2000 times per second, is quite satisfactory for observing audio frequencies which are being repeated continuously, but for transient audio frequencies the switching rate must be much higher. An example would be in the reception of a meteor Doppler whistle on two similar receivers which may be tuned to transmitters on different frequencies, or on two receivers at different locations with the intelligence being transmitted to one common location and presented simultaneously on one cathode-ray tube. The frequency of a Doppler whistle varies from zero to a value of the order of 800 cycles per second. In order that the instantaneous frequency may be determined at any instant it must be sampled at least three times for each cycle, but a higher rate is more desirable — e.g., five times, or more, per cycle. With the electronic switch described here two transient frequencies as high as 20 kilocycles per second can be observed simultaneously by sampling each frequency at least five times per cycle.

In the oscilloscope used, the vertical deflecting plates must be brought out to terminals on the front panel for best results. The mixed signal from the electronic switch is applied to one vertical deflection plate and the sweep separation voltage is applied to the other plate.

### Circuit Description

In Fig.1  $V_1$  is a multivibrator whose frequency can be varied from approximately twenty to one hundred thousand times per second by the dual potentiometer  $P_{1a}$ ,  $P_{1b}$ . The output from each plate of this tube is further squared in  $V_2$ . Since the load resistors of  $V_2$  are very small, a sharp rise and fall time of the voltage of the square wave is obtained. One of the audio signals to be examined is coupled to the control grid of  $V_4$  through potentiometer  $P_2$  and the other signal through  $P_5$  to the control grid of  $V_5$ . The square waves from  $V_2$  are connected to the suppressor grids of  $V_4$  and  $V_5$  and these tubes are turned on alternately. Since they have a common plate load, samples of both input signals will appear at the plate in sequence. A type-1N34 crystal is connected from each suppressor to ground to prevent the gating pulse driving the suppressor positive

during the instant it is turned on. The gated amplifiers have a voltage gain of approximately 18.

The common output of  $V_4$  and  $V_5$  is connected to the grid of  $V_6$  which is a cathode follower with the grid resistor returned to a tap on the cathode load. This will allow an output voltage of the order of 65 volts, peak-to-peak, to appear at the cathode before the negative part of the signal is clipped off due to the action of the cathode follower.

Sweep separation is obtained by using the square wave which is applied to the suppressor grid of  $V_4$  and coupled through  $P_3$  to an output terminal which can be connected to one of the vertical deflection plates on the oscilloscope. This causes the sweep to be deflected in one direction when  $V_4$  is turned on and in the opposite direction when  $V_5$  is on, thus forming what appear to be two different horizontal sweeps, having an audio signal on one completely independent of the other.

$P_4$  is a potentiometer in the cathode of  $V_5$  which is adjusted to produce exact balance in the gated amplifiers,  $V_4$  and  $V_5$ . The method of adjustment is to apply the output of the switch to one vertical deflecting plate of the oscilloscope with the sweep separation output terminal disconnected, and then adjust  $P_4$  until there is no sweep separation. Once set up it should require no further adjustment during normal operation.

The frequency of the multivibrator,  $V_1$ , is not critical and normally requires no adjustment except when observing fairly high audio frequencies that happen to be nearly submultiples of the multivibrator frequency. In this case small breaks appear in the sweep due to switching rate. A slight movement of the frequency control in either direction will cause these breaks to move along the sweep at such a speed that they will no longer be noticeable.

The power supply is of the conventional type and uses a miniature type-6X4 tube as a rectifier. The electronic switch draws about 40 milliamperes at 240 volts, unregulated. Its dimensions are 10 by 6 by 6 inches.

Figs. 2 and 3 are photographs of the electronic switch.
